We construct a class of projected $SO(5)$ models where the Gutzwiller constraint of no-double-occupancy is implemented exactly. We introduce the concept of projected $SO(5)$ symmetry where all static correlation functions are exactly $SO(5)$ symmetric and discuss the signature of the projected $SO(5)$ symmetry in dynamical correlation functions. We show that this class of projected $SO(5)$ models can give a realistic description of the global phase diagram of the high T_c superconductors and account for many of their physical properties.

I. INTRODUCTION

Recently, a unified theory of antiferromagnetism (AF) and superconductivity (SC) has been proposed for the high T_c cuprates [1]. This theory is based on the $SO(5)$ symmetry between AF and SC, and offers a unified description of the global phase diagram for this class of materials. While the theory was originally proposed as a effective field theory description, it was soon realized that the $SO(5)$ symmetry could be implemented exactly at a microscopic level [2–6], and it can also be checked numerically in common strongly correlated models such as the $t - J$ model [7–9]. While the phase diagram [1,10–12] and collective excitations [13,14] in the SC state derived from these $SO(5)$ models bear strong resemblance with the high T_c cuprates, and a number of novel experimental predictions have been made [15–19], the Mott insulating behavior at half-filling is a puzzling aspect which challenges the fundamental validity of the $SO(5)$ models [20–23]. To be more precise, the exact $SO(5)$ symmetry requires collective charge two excitation at half-filling to have the same mass as the collective spin wave excitations. This condition is clearly violated in a Mott insulating system where all charge excitations measured with respect to a particle hole symmetric point have a large energy gap of few eV, while the spin wave excitations are massless. In the original $SO(5)$ proposal, it was pointed out that this situation is analogous to a easy-axis antiferromagnet in a external uniform field, and a $SO(5)$ symmetry breaking term at half-filling was introduced in order to describe this asymmetric behavior between spin and charge. The chemical potential also introduces a $SO(5)$ symmetry breaking term, however, it was shown that these two terms could compensate each other [1,8] so that the *static potential* governing the $SO(5)$ superspin could still be $SO(5)$ symmetric.

Since the asymmetry between the charge and spin excitations at half-filling is of the order of the Coulomb energy scale U , the $SO(5)$ symmetry breaking terms must also be of that order. Since there are various types of symmetry breaking terms, one might hope that their effects could partially cancel each other to arrive at a qualitatively correct picture. However, this type of cancellation is very delicate, and approximate calculations could easily lead to erroneous conclusions. In particular, one is interested in which physical properties could exhibit $SO(5)$ symmetric properties in the limit when the Coulomb gap is taken to infinity. For example, one could ask the following questions:

1) One of the hallmarks of the $SO(5)$ symmetry is not only the degeneracy between the AF and SC states at a given chemical potential, but the approximate degeneracy among all mix-states interpolating between AF and SC, *i.e.* the independence of the ground state energy on the superspin angle. What is the potential barrier separating the AF and SC states at their degeneracy point in the limit $U \rightarrow \infty$? If there is a large energy barrier in this limit, one would argue that the concept of $SO(5)$ symmetry is not a useful one, at least not for quantitative calculations. On the other hand, if the potential barrier is finite and small in the $U \rightarrow \infty$ limit, the concept of a approximate $SO(5)$ symmetry would be a useful one.

2) Exact $SO(5)$ symmetry predicts four massless collective modes. In the half-filled AF state, besides the two conventional massless spin wave modes, the exact $SO(5)$ symmetry predicts a massless doublet of $\pi^\pm$ modes, with charge ± 2 . However, a Mott insulator has a large gap to all charge excitations. Therefore, it is clear that one of the $\pi^\pm$ has to be projected out of the spectrum in the limit $U \rightarrow \infty$, say the π^+ mode carrying charge $+2$. What happens

to the rest of the Goldstone modes, the π^- mode carrying charge -2 and the π^α triplet mode of the SC state? In the $U \rightarrow \infty$ limit, can they all be simultaneously massless at the transition point between AF and SC? Since the pure SC state can only be reached with a finite doping concentration, is it possible that the Gutzwiller projection does not affect the π^α triplet mode of the SC state?

In order to address these questions, it is desirable to construct a low energy effective theory without any parameters of the order of the Coulomb scale U . In this work, we construct a class of projected $SO(5)$ models which treat the Gutzwiller constraint exactly and locally on every site. We use this model to answer the physical questions posed above and show that the answers are affirmative. In the $U \rightarrow \infty$ limit, when the Gutzwiller constraint is implemented exactly, the ground state energy can still be $SO(5)$ symmetric and independent of the superspin direction. After projecting out the π^+ mode, all other Goldstone modes remain massless at the symmetric point. The dispersion relation of the collective modes bear unique signature of the projected $SO(5)$ symmetry. Furthermore, the π^α triplet modes of the pure SC states are unaffected by the Gutzwiller projection. These properties define the concept of a projected $SO(5)$ symmetry ($pSO(5)$), whose properties and consequences we shall explore in this paper.

The fundamental quantity in the $SO(5)$ theory is the locally defined five component superspin vector $n_a(x) = (n_1, n_2, n_3, n_4, n_5)$ describing the local AF and SC order parameters respectively. In the nonlinear σ model formalism, these are treated as mutually commuting coordinates and their dynamics is given by their conjugate momenta $p_a(x) = (p_1, p_2, p_3, p_4, p_5)$. The charge operator is the angular momentum in the $n_1 - n_5$ plane:

$$Q(x) = L_{15} = n_1 p_5 - n_5 p_1 \quad (1.1)$$

Implementing the Gutzwiller constraint corresponds to requiring

$$Q(x) \leq 0 \quad (1.2)$$

for every local $SO(5)$ rotor. From equations (1.1) and (1.2) and subsequent discussions, we shall see that the Gutzwiller projection in the $SO(5)$ formalism corresponds to going from a fully symmetric $SO(5)$ rotor model to a *chiral* $SO(5)$ rotor model, where both the static potential of the individual rotors and the coupling between the rotors are still $SO(5)$ symmetric, but the rotors are constrained to rotate only in one sense in the $n_1 - n_5$ plane, consistent with (1.2). This observation reveals a deep connection between the Gutzwiller projection and the Lowest-Landau-Level (LLL) projection in the fractional quantum Hall effect [24]. To be more precise, the Gutzwiller projection represented by equations (1.1) and (1.2) is analogous to the LLL projection, where all states in the LLL have a definite sign of angular momentum. The LLL projection can be analytically implemented by separating the cyclotron degrees of freedom from the guiding center degrees of freedom, which amounts to changing the commuting property between the X and Y coordinates to a canonically conjugate commutation relation:

$$[X, Y] = i l_0 \quad (1.3)$$

where l_0 is the Landau length. Exploiting this analogy, we find that the original $SO(5)$ model can be fully Gutzwiller projected without changing its form, if one imposes the simple quantization condition between the superconducting components of the superspin vector:

$$[n_1, n_5] = i/2 \quad (1.4)$$

In the symmetric $SO(5)$ model, the wave function of the $SO(5)$ rotors are functions of the local coordinates n_1 and n_5 , while the projected $SO(5)$ model only depends on their holomorphic combination $z = n_1 - i n_5$ and is independent of their anti-holomorphic combination $\bar{z} = n_1 + i n_5$. This way, we arrive at a natural projection of the $SO(5)$ model where the local Gutzwiller constraint is taken into account exactly, and the resulting model is free of the large Coulomb U parameter. Because the functional form of the symmetric $SO(5)$ model remain the same and only the quantization condition is modified upon projection, many important properties associated with the $SO(5)$ symmetry remain. The central hypothesis of the $SO(5)$ theory is that this projected model is quantitatively accurate in describing both the static and dynamic properties of the high T_c cuprates, and we shall compare the properties of this model with the phenomenology of the high T_c systems.

II. CONSTRUCTION OF PROJECTED $SO(5)$ MODELS

We begin with the symmetric $SO(5)$ Hamiltonian defined on a lattice,

$$\begin{aligned}
H = & \Delta \sum_x L_{ab}^2(x) - J \sum_{\langle xx' \rangle} n_a(x) n_a(x') \\
& + V \sum_{\langle xx' \rangle} L_{ab}(x) L_{ab}(x')
\end{aligned} \tag{2.1}$$

where $n_a(x)$ denotes the five component superspin vector on a given site, and $L_{ab}(x)$ is the $SO(5)$ symmetry generator,

$$L_{ab} = n_a p_b - n_b p_a \tag{2.2}$$

expressed here in terms of the superspin vector n_a and its canonically conjugate momenta p_a ,

$$[n_a, p_b] = i\delta_{ab} \tag{2.3}$$

This lattice quantum non-linear σ model can be rigorously derived as the low energy limit of a microscopic $SO(5)$ ladder model [5,6]. On the ladder, the rung $SO(5)$ singlet state is the vacuum $|\Omega\rangle$, from which the lowest $SO(5)$ multiplet $|a\rangle = t_a^\dagger |\Omega\rangle$ is created by a quintet of Bose creation operators, which satisfy

$$[t_a, t_b^\dagger] = \delta_{ab}, \quad t_a |\Omega\rangle = 0 \tag{2.4}$$

Here, $a = 2, 3, 4$ denote the triplet (magnon) states, and $a = 1, 5$ are the hole and particle pair states. (see Fig. (1)). The superspin coordinates are microscopically constructed using these lattice bosons,

$$n_a = \frac{1}{\sqrt{2}}(t_a + t_a^\dagger) \quad p_a = \frac{1}{i\sqrt{2}}(t_a - t_a^\dagger) \tag{2.5}$$

FIG. 1. Schematic representation of the singlet state, the triplet magnon states and the hole and particle pair states.

Due to their microscopic origin, these bosonic states are hard-core bosons, in the sense that one can not define two of them on the same rung. The Δ term in equation (2.1) describes the gap energy of the magnon and the pair states, the J term stands for the hopping and the spontaneous creation/destruction process of these states, and the V term describes their nearest-neighbor interaction. This quantum nonlinear σ model can in principle also be derived in higher dimensions from a microscopic $SO(5)$ symmetric model [2–4], by introducing a superspin vector as a Hubbard-Stratonovich decoupling field, and integrate out the fermionic degrees of freedom in a gradient expansion. However, we shall proceed more heuristically here [25]. For a two dimensional system, one can imagine that the quantum σ model Hamiltonian is obtained from a “block spin” type of coarse-graining of the microscopic electron Hamiltonian, and is defined on a lattice with twice the lattice constant compared to the microscopic electron model. (This doubled unit cell is the minimal size needed to define the local AF and d wave SC order parameters). Therefore, each site x in the effective model correspond to a plaquette of the microscopic electron model. (On a ladder, this corresponds to going from the lattice sites to ladder rungs). The $SO(5)$ singlet state $|\Omega\rangle$ corresponds to a “RVB” type of singlet state, while the five-fold states $t_a^\dagger |\Omega\rangle$ describe the triplet magnon states, and the d -wave hole and particle pair states on a plaquette. Unlike the ladder case, the magnon and the d -wave pair states could condense in the ground state to form AF and SC broken symmetry states. In fact, Eder [25] has recently shown that properties of the AF states can be described by a coherent state of magnon condensation on top of a uniform spin liquid state. Our model therefore describes competition among the “RVB” type of singlet vacuum and the two forms of broken symmetry order.

While it is reasonable to take J and V to be approximately equal for magnons and pairs, the gap energy Δ for the neutral magnons and the charged pairs are very different in the insulating state at half-filling. In fact, their difference is of the order of the insulating gap U at half-filling. Taking into account the hard-core condition and neglecting the

nearest-neighbor interaction V for now (it has higher powers of time and space derivatives in the continuum limit), we can express the general anisotropic $SO(5)$ model as

$$H = \Delta_s \sum_x t_\alpha^\dagger t_\alpha(x) + \Delta_c \sum_x t_i^\dagger t_i(x) - J_s \sum_{\langle xx' \rangle} n_\alpha(x) n_\alpha(x') - J_c \sum_{\langle xx' \rangle} n_i(x) n_i(x') \quad (2.6)$$

In this paper we shall use the convention where $a, b, \dots = 1, 2, 3, 4, 5$ denote the superspin indices, $\alpha, \beta, \dots = 2, 3, 4$ denote the spin indices and $i, j = 1, 5$ denote the charge indices, and repeated indices are summed over. The main focus of our paper is to consider the limit where $\Delta_c \gg \Delta_s$.

Let us define the charge eigen-operators t_h and t_p as

$$t_1 = \frac{1}{\sqrt{2}}(t_h + t_p) \quad t_5 = \frac{1}{i\sqrt{2}}(t_h - t_p) \quad (2.7)$$

From this definition, it is clear that $t_h^\dagger$ is the creation operator for a hole pair and $t_p^\dagger$ is the creation operator for a particle pair. We can introduce a chemical potential term

$$H_\mu = \mu \sum_x (t_p^\dagger t_p(x) - t_h^\dagger t_h(x)) \quad (2.8)$$

to describe the effects of doping. In the presence of this chemical potential term, the gap energy of the hole and particle pairs are $\Delta_c - \mu$ and $\Delta_c + \mu$ respectively. A chemical potential of the order of the charge gap Δ_c is needed to induce a metal-insulator transition in this system. Near such a transition point, the gap energy of the hole pair

$$\tilde{\Delta}_c = \Delta_c - \mu \quad (2.9)$$

can be comparable to the spin gap Δ_s , while the gap towards a particle pair excitation is of the order of twice the charge gap, and needs to be projected out of the spectrum in the low energy limit.

Therefore, within this formalism, the Gutzwiller projection is equivalent to restricting ourselves to the projected Hilbert space where

$$t_p(x)|\Psi\rangle = 0 \quad (2.10)$$

at every site x . Within this projected Hilbert space, the projected Hamiltonian takes the form

$$H = \Delta_s \sum_x t_\alpha^\dagger t_\alpha(x) + \tilde{\Delta}_c \sum_x n_i(x) n_i(x) - J_s \sum_{\langle xx' \rangle} n_\alpha(x) n_\alpha(x') - J_c \sum_{\langle xx' \rangle} n_i(x) n_i(x') \quad (2.11)$$

This Hamiltonian has no parameters of the order of U , and it is reasonable to expect $\Delta_s \sim \tilde{\Delta}_c$ and $J_s \sim J_c$. We see that the form of the Hamiltonian hardly changes from the unprojected model, but the definition of n_1 and n_5 is changed from

$$n_1 = \frac{1}{\sqrt{2}}(t_1 + t_1^\dagger) = \frac{1}{2}(t_h + t_p + t_h^\dagger + t_p^\dagger) \\ n_5 = \frac{1}{\sqrt{2}}(t_5 + t_5^\dagger) = \frac{1}{2i}(t_h - t_p - t_h^\dagger + t_p^\dagger) \quad (2.12)$$

to

$$n_1 = \frac{1}{2}(t_h + t_h^\dagger) \quad n_5 = \frac{1}{2i}(t_h - t_h^\dagger) \quad (2.13)$$

From equation (2.12), we see that n_1 and n_5 commute with each other before the projection. However, after the projection, they acquire a nontrivial commutation relation, as can be seen from equation (2.13):

$$[n_1, n_5] = i/2 \quad (2.14)$$

Therefore, the Gutzwiller projection can be analytically implemented in the $SO(5)$ theory by retaining the form of the Hamiltonian and change only the quantization condition.

III. ANALOGY WITH LOWEST-LANDAU-LEVEL PROJECTION

The discussions outlined above reveal a deep connection between the Gutzwiller projection within the $SO(5)$ formalism and the projection onto the lowest Landau level (LLL) in the context of the fractional quantum Hall effect. Consider the problem of a charged particle in a strong magnetic field B and a rotationally symmetric potential $V(X, Y)$. In the absence of a magnetic field, all eigenstates form irreducible representations of the two dimensional rotation group $O(2)$, characterized by integral eigenvalues of the angular momentum operator

$$L_Z = XP_Y - YP_X \quad (3.1)$$

However, in the presence of a strong magnetic field and projected into the LLL, only negative eigenvalues of L_Z are realized. This is analogous to the situation encountered here. The local charge operator in the $SO(5)$ theory takes the form of the angular momentum in the $n_1 - n_5$ plane as given by equation (1.1). When doubly occupied sites are locally projected out, the local charge operator, or the angular momentum in the $n_1 - n_5$ plane, takes only negative values. Since the chemical potential couples directly the angular momentum in the $n_1 - n_5$ plane, it plays the role of a fictitious magnetic field threading every $SO(5)$ rotor in the $n_1 - n_5$ plane. The Landau level spacing $\hbar\omega_c$ is analogous to the charge gap Δ_c encountered here, and both are taken to be infinity in the projected models. After the projection, the Hamiltonian in the Landau level problem retains its $O(2)$ symmetric form,

$$H = V(X, Y) \quad (3.2)$$

although a new quantization condition is imposed between X and Y , as given by equation (1.3). This is analogous to the observation we made here that the Hamiltonian formally retains a $SO(5)$ symmetric form after the projection (2.10), but the quantum dynamics is changed due to the non-trivial commutator between n_1 and n_5 . In both cases only a part of the full symmetry multiplets remain after the projection. However, the formal symmetry of the Hamiltonian has direct physical manifestations despite the projection. For example, in the LLL problems, semi-classical orbits of the guiding center coordinates are still $O(2)$ symmetric. In our case, we shall see that the static potential for the superspin vector can still be $SO(5)$ invariant despite the projection.

Perhaps the most explicit way to establish the precise connections between these two problems is to consider the constraints on the wave function. In the symmetric gauge of the LLL problem, the annihilation operator for the cyclotron coordinates takes the form [24]

$$a = \partial_{\bar{z}} + z/4 \quad (3.3)$$

where $z = X + iY$ and $\bar{z} = X - iY$. Projection onto LLL requires

$$a\Psi(z, \bar{z}) = 0 \quad (3.4)$$

which determines the form of the LLL wave function to be

$$\Psi(z, \bar{z}) = f(z)e^{-z\bar{z}/4} \quad (3.5)$$

where $f(z)$ is a holomorphic function of z only. This holomorphic condition also places strong constraints in many-body systems and led to the celebrated Laughlin's wave function. Our no-double-occupancy constraint (2.10) is analogous to the LLL constraint (3.4). In fact from equations (2.7) and (2.12), we obtain

$$t_p = \frac{1}{2}(z + 2\partial_{\bar{z}}) \quad (3.6)$$

where $z = n_1 - in_5$ and $\bar{z} = n_1 + in_5$. For a single unprojected $SO(5)$ rotor, the wave function $\Psi(n_a)$ is a function of the superspin coordinates. However, the Gutzwiller projection (2.10) restricts the wave function to be

$$\Psi(n_1, n_2, n_3, n_4, n_5) = f(z = n_1 - in_5, n_2, n_3, n_4)e^{-z\bar{z}/2} \quad (3.7)$$

where $f(z, n_2, n_3, n_4)$ is a holomorphic function of z . For a collection of $SO(5)$ rotors, the superspin coordinates are themselves functions of the lattice sites x , and $\Psi[n_a(x)]$ is a functional of the superspin coordinates at each site. For the projected $SO(5)$ models, this functional is restricted to take the form

$$\Psi[n_a(x)] = f(z(x), n_a(x)) \prod_x e^{-z\bar{z}(x)/2} \quad (3.8)$$

where $f(z(x), n_\alpha(x))$ is a holomorphic functional of $z(x) = n_1(x) - in_5(x)$.

The formal but precise analogy between the two types of projection allows us to introduce the concept of a chiral $SO(5)$ rotor. This is a system of rotors with $SO(5)$ invariant potential and coupling, however, the rotation within the $n_1 - n_5$ plane is chiral, *i.e.* only one sense of the rotation is allowed. Such a system of chiral $SO(5)$ rotors is described by the wave functional in equation (3.8).

IV. $SO(5)$ SYMMETRY OF THE GROUND STATE ENERGY

Having discussed the general notions of the projected $SO(5)$ model, we are now in a position to explore the phase diagram of this model. As we commented earlier, the projected $SO(5)$ model describes the competition and unification of the spin liquid, AF and the SC states. In the original unprojected $SO(5)$ symmetric model, not only are the AF and SC states degenerate in energy, but they are also degenerate with all the intermediate coexistence states. This points out a route from AF to SC with no potential barrier, and introduces the concept that the metal-insulator transition in the high T_c systems can be viewed as a smooth rotation of the $SO(5)$ superspin. One of the key questions to be answered in this work is what happens to the picture in the case of projected $SO(5)$ symmetry.

In anticipation of the competition of the states discussed above, we construct a class of variational wave functions in the coherent state representation:

$$|\Psi\rangle = \prod_x (\cos \theta(x) + \sin \theta(x)(m_\alpha(x)t_\alpha^\dagger(x) + \Delta(x)t_h^\dagger(x)))|\Omega\rangle \quad (4.1)$$

Here $|\Omega(x)\rangle$ denotes a local singlet state defined by $t_\alpha(x)|\Omega(x)\rangle = t_h(x)|\Omega(x)\rangle = 0$ and $|\Omega\rangle$ is a product state of these local singlets, $|\Omega\rangle = \prod_x |\Omega(x)\rangle$. $\theta(x)$ is a local variational parameter describing the competition between long range order and quantum disorder. For $\theta(x) = 0$ our variational wave function describe a spin singlet ground state, while a non-zero value of θ describes a coherent state formed by the local singlet, the magnon or the hole pair state. This wave function is a generalization of the coherent state description of a AF state in terms of a magnon condensate [6,25]. As we shall see from the following equation (4.2), $\sin 2\theta$ stands for the length of the $SO(5)$ superspin vector. $m_\alpha(x)$ and $\Delta(x)$ are general complex variational parameters describing the local amplitude for magnons and hole pairs. We notice that this wave function satisfies both the Gutzwiller constraint (2.10) and the hard-core constraint for magnons and hole pairs exactly. It is easy to see that

$$\begin{aligned} \langle \Psi | n_\alpha(x) | \Psi \rangle &= \frac{1}{\sqrt{2}} \sin 2\theta(x) \text{Re}(m_\alpha(x)) \\ \langle \Psi | n_1(x) | \Psi \rangle &= \frac{1}{2} \sin 2\theta(x) \text{Re}(\Delta(x)) \\ \langle \Psi | n_5(x) | \Psi \rangle &= \frac{1}{2} \sin 2\theta(x) \text{Im}(\Delta(x)) \end{aligned} \quad (4.2)$$

where Re and Im denote the real and imaginary parts of a complex number. The coupling terms in the projected $SO(5)$ Hamiltonian depend only on $n_\alpha(x)$, $n_1(x)$ and $n_5(x)$. Therefore, the coupling energy depends only on the real part of $m_\alpha(x)$ while it depends on both the real and imaginary parts of $\Delta(x)$. Therefore, for discussing the ground state wave functions, we can assume without loss of generality that $m_\alpha(x)$ is real and $\Delta(x) = m_1(x) + im_5(x)$. The normalization condition $\langle \Psi | \Psi \rangle = 1$ can be implemented by the constraint that

$$m_\alpha^2(x) = (m_1^2 + m_5^2 + m_\alpha^2)(x) = 1 \quad (4.3)$$

Therefore, we see that although we have completely projected out the particle pair states, the local degrees of freedom can still be represented by a vector on a five dimensional sphere.

Uniform states are obtained by taking all parameters to be constant. For $\Delta = 0$ and $\sin 2\theta \neq 0$, our wave function $|\Psi\rangle$ describes a pure AF state with the following properties:

$$\begin{aligned} \langle \Psi | Q | \Psi \rangle &= \langle \Psi | \sum_x t_h^\dagger t_h(x) | \Psi \rangle = 0 \\ \langle \Psi | N_\alpha | \Psi \rangle &= \langle \Psi | \sum_x n_\alpha(x) | \Psi \rangle = N \frac{1}{\sqrt{2}} \sin 2\theta m_\alpha \\ \langle \Psi | S_\alpha | \Psi \rangle &= \langle \Psi | \sum_x i \epsilon^{\alpha\beta\gamma} t_\beta^\dagger t_\gamma(x) | \Psi \rangle = 0 \end{aligned}$$

$$\langle \Psi | S^2 | \Psi \rangle = \langle \Psi | \left(\sum_x S(x) \right)^2 | \Psi \rangle = N 2 \sin^2 \theta + N \sin^4 \theta (1 - m_\alpha^4) \quad (4.4)$$

where N is the number of lattice sites. Equation (4.4) describes a half-filled state with a macroscopic Neel magnetization, and vanishing uniform magnetization. Furthermore, this state is composed as a linear superposition of eigenstates with different values of the total spin, and the fluctuation of the total spin scales like $\sqrt{\langle S^2 \rangle} \propto \sqrt{N}$, just as one expects from a standard Neel state.

On the other hand, for $m_\alpha = 0$ and $\sin 2\theta \neq 0$, $|\Psi\rangle$ describes a pure SC state with the following properties:

$$\begin{aligned} \langle \Psi | Q | \Psi \rangle &= \langle \Psi | \sum_x t_h^\dagger t_h(x) | \Psi \rangle = N \sin^2 \theta \\ \langle \Psi | N_1 + i N_5 | \Psi \rangle &= \langle \Psi | \sum_x (n_1 + i n_5)(x) | \Psi \rangle = N \frac{1}{2} \sin 2\theta (m_1 + i m_5) \\ \langle \Psi | Q^2 | \Psi \rangle - \langle \Psi | Q | \Psi \rangle^2 &= N \sin^2 \theta \cos^2 \theta \end{aligned} \quad (4.5)$$

Equation (4.5) describes a state with a finite doping density and a finite SC order parameter. Just as in the standard BCS case, this state is composed as a linear superposition of eigenstates with different values of the total charge, and the fluctuation of the total charge scales like $\sqrt{\langle Q^2 \rangle - \langle Q \rangle^2} \propto \sqrt{N}$, just as one expects from a standard SC state.

However, besides these two *pure* states, there is a class of *mixed* states which interpolates between the pure AF and SC states. Taking $m_1 = \sin \alpha$ and $m_2 = \cos \alpha$, we see that the mixed states have the following property:

$$\begin{aligned} \langle \Psi | Q | \Psi \rangle &= N \sin^2 \theta \sin^2 \alpha \\ \langle \Psi | N_1 + i N_5 | \Psi \rangle &= N \frac{1}{2} \sin 2\theta \sin \alpha \\ \langle \Psi | N_2 | \Psi \rangle &= N \frac{1}{\sqrt{2}} \sin 2\theta \cos \alpha \end{aligned} \quad (4.6)$$

Therefore, we see that there is a continuous family of intermediate mixed states interpolating between the pure AF state at half-filling and the pure SC state with finite doping density. As the $SO(5)$ angle α rotates continuously from a pure AF state with $\alpha = 0$ to a pure SC state with $\alpha = \pi/2$, the hole density of the mixed state interpolates continuously between these two limits. Therefore, our wave function gives a unified description of AF and SC and points out a precise route from AF to SC as the doping level is varied. In order for this route, or small deviations from this route, to be physically realized in the high T_c superconductors, we have to demonstrate that there is no large energy barrier for the intermediate mixed states, or that the ground state energy is approximately independent of the $SO(5)$ mixing angle α . In particular, we have to show that the energy barrier is independent of the Hubbard energy U , in the limit of large U . In the following, we shall investigate this question.

The energy functional $\langle \Psi | H | \Psi \rangle$ describes the coupling between these five dimensional vectors $m_\alpha(x)$, and it is given by

$$\begin{aligned} \langle \Psi | H | \Psi \rangle &= E(\theta(x), m_\alpha(x)) \\ &= -\frac{J_s}{2} \sum_{xx'} \sin 2\theta(x) \sin 2\theta(x') m_\alpha(x) m_\alpha(x') - \frac{J_c}{4} \sum_{xx'} \sin 2\theta(x) \sin 2\theta(x') m_i(x) m_i(x') \\ &\quad + \Delta_s \sum_x \sin^2 \theta(x) m_\alpha^2(x) + \tilde{\Delta}_c \sum_x \sin^2 \theta(x) m_i^2(x) \end{aligned} \quad (4.7)$$

This ground state energy functional describes a systems of coupled rotors satisfying the constraint (4.3). At the point $J_c = 2J_s$ and $\tilde{\Delta}_c = \Delta_s$ in parameter space, this rotor model is exactly $SO(5)$ symmetric. This is a central observation of this work.

From this consideration we learn a very important lesson about the compatibility of the Mott insulating gap and the idea of a smooth $SO(5)$ rotation from AF to SC. As we have seen, the large asymmetry between the charge and spin gap at half-filling necessitates the removal of the $Q(x) > 0$ part of the $SO(5)$ multiplets, therefore, the dynamics close to half-filling has to be modified. But the static potential governing the transition from AF to SC can remain $SO(5)$ symmetric, and in particular, the energy barrier separating these two states can remain small in the limit where the Mott insulating gap tends to infinity.

We also observe a crucial difference between the projected and the unprojected $SO(5)$ models. In the unprojected $SO(5)$ model with the full $SO(5)$ symmetry, AF and SC states are degenerate at half-filling, and the rotation between

these two states can be continuously performed without changing the density to going away from half-filling. This case is similar to the well-known degeneracy between the CDW state and the s wave SC state for the negative U Hubbard model at half-filling. In the projected $SO(5)$ model, where all particle pair states have been locally removed, the $SO(5)$ rotation from the AF to SC states are accompanied by the continuous change of the hole density, and a pure SC state can only be reached at a finite critical hole doping density $\rho_c = \sin^2 \theta$. While the unprojected $SO(5)$ symmetry is only valid at half-filling, the projected $SO(5)$ symmetry can be valid for a range of doping concentration $0 < \rho < \rho_c$, since all these doping concentrations correspond to the same value of the chemical potential $\mu = \mu_c$ at which the ground state energy (4.7) is $SO(5)$ symmetric.

However, it should be pointed out that the projected $SO(5)$ symmetry at $\mu = \mu_c$ has only been demonstrated within the variational mean field approximation. This corresponds to the semiclassical limit, and becomes exact only in the large s limit, where s labels the representation of the local $SO(5)$ group at a given site. Quantum fluctuations can be systematically investigated as a $1/s$ expansion. Assuming uniform ground states, we have studied the effect of zero point fluctuations in Sec. VII and found that at $\mu = \mu_c$, the intermediate mixed states have slightly higher energy than the AF and SC state. Therefore, quantum fluctuation leads to a slight breaking of the projected $SO(5)$ symmetry. The important point here is that this symmetry breaking effect can be systematically controlled in the semi-classical $1/s$ expansion, and certainly is independent of the Coulomb energy scale U . This fluctuation would induce a first order transition and predict phase separation of AF and SC states at $\mu = \mu_c$. However, there are also other competing interactions such as nearest-neighbor and next-nearest-neighbor interactions which tend to reduce the barrier, and could also lead to non-uniform states like stripes. Due to the complexity of the calculations, we shall defer the detailed studies of these competing effects to future works.

V. PHASE DIAGRAM

In this section we investigate the phase diagram of the projected $SO(5)$ model within the framework of the variational wave function (4.1). Taking uniform values of the variational parameters θ , $m_x = \cos \alpha$, $m_1 = \sin \alpha$ and $m_y = m_z = m_5 = 0$, the variational energy in (4.7) reduces to

$$\frac{E(\theta, \alpha)}{N} = -J_s \sin^2 2\theta \cos^2 \alpha - \frac{J_c}{2} \sin^2 2\theta \sin^2 \alpha + \Delta_s \sin^2 \theta \cos^2 \alpha + \tilde{\Delta}_c \sin^2 \theta \sin^2 \alpha \quad (5.1)$$

In the following, we shall mainly study the $SO(5)$ symmetric case, and take $J_c = 2J_s = 2J$. Defining $x = \sin^2 \theta$ and $y = \cos^2 \alpha$, and the dimensionless coupling constants $\epsilon \equiv \frac{E(x, y)}{4JN}$, $\delta_s \equiv \frac{\Delta_s}{4J}$ and $\tilde{\delta}_c \equiv \frac{\tilde{\Delta}_c}{4J}$, we obtain

$$\epsilon(x, y) = x^2 - x + \tilde{\delta}_c x + (\delta_s - \tilde{\delta}_c)xy \quad (5.2)$$

We shall minimize (5.2) with respect to x and y , subject to the condition that $0 \leq x, y \leq 1$. The phase diagram can be plotted in the two dimensional parameter space of $\tilde{\delta}_c$ and δ_s . We notice that $\epsilon(x, y)$ depends linearly on y , therefore, for $\delta_s > \tilde{\delta}_c$ we obtain $y_{min} = 0$ and

$$\begin{aligned} 0 < x_{min} = \frac{1 - \tilde{\delta}_c}{2} < 1 & \text{ for } -1 < \tilde{\delta}_c < 1 \\ x_{min} = 0 & \text{ for } \tilde{\delta}_c > 1 \\ x_{min} = 1 & \text{ for } \tilde{\delta}_c < -1 \end{aligned} \quad (5.3)$$

Similarly, for $\delta_s < \tilde{\delta}_c$ we obtain $y_{min} = 1$ and

$$\begin{aligned} 0 < x_{min} = \frac{1 - \delta_s}{2} < 1 & \text{ for } -1 < \delta_s < 1 \\ x_{min} = 0 & \text{ for } \delta_s > 1 \\ x_{min} = 1 & \text{ for } \delta_s < -1 \end{aligned} \quad (5.4)$$

From these equation, we can determine the phase diagram as shown in Fig. (2).

FIG. 2. Phase diagram of the projected $SO(5)$ model in the δ_s versus $\tilde{\delta}_c$ plane. Phase boundaries are depicted by the solid lines. Variation of the chemical potential traces out a one dimensional trajectory as shown on the dotted line.

There are seven different phases on this phase diagram. $x_{min} = 0$ corresponds to a quantum disordered singlet state with no condensed bosons. $x_{min} = 1$ and $y_{min} = 0$ corresponds to a quantum disordered state with completely filled hole pairs. $x_{min} = 1$ and $y_{min} = 1$ corresponds to a quantum disordered state with completely filled magnons. $0 < x_{min} < 1$ and $y_{min} = 1$ describe a pure AF phase, while $0 < x_{min} < 1$ and $y_{min} = 0$ describes a pure SC phase. When $-1 < \delta_s = \tilde{\delta}_c < 1$ a continuous family of mixed AF/SC states labeled by a free superspin angle $0 < \alpha < \pi/2$ is realized, while for $\delta_s = \tilde{\delta}_c < -1$ a continuous family of quantum disordered states labeled by a free superspin angle $0 < \alpha < \pi/2$ is obtained.

The system traces out a one dimensional trajectory in this two dimensional phase diagram as the chemical potential is increased, as depicted in Fig. (2). Increasing the chemical potential decreases the $\tilde{\delta}_c$ parameter while holding δ_s constant. δ_s describes the degree of quantum spin fluctuations in the system, since in the AF phase, the size of the Neel moment

$$m_{AF} = \sqrt{\frac{1}{2}(1 - \delta_s^2)} \quad (5.5)$$

decreases with increasing δ_s . For $\delta_s < 1$, the system goes through a phase transition from AF to SC at $\mu = \mu_c = \Delta_c - \Delta_s$. At this critical value of the chemical potential, the θ parameter remains fixed, but the α parameter changes continuously from 0 to $\pi/2$, and correspondingly, the density changes from 0 to

$$\rho_c \equiv \sin^2 \theta = x_{min} = \frac{1 - \delta_s}{2} \quad (5.6)$$

This behavior gives a density versus chemical potential diagram as shown in Fig. (3).

FIG. 3. Density versus chemical potential relation in the projected $SO(5)$ model. Unlike the case of a generic first order transition, the ground state in the density range $0 < \rho < \rho_c$ is uniform, rather than phase separated.

As we see, for densities in the range $0 < \rho < \rho_c$, the system is infinitely compressible since $\partial\rho/\partial\mu = \infty$. For $\mu > \mu_c$ or $\rho > \rho_c$, the system has a finite compressibility of $\partial\rho/\partial\mu = 1/8J$.

It is interesting to plot both the AF and the SC order parameters $\langle n_1 \rangle$ and $\langle n_2 \rangle$ as a function of the density for the whole range of $0 < \rho < 1$. We will restrict to the case of $0 < \delta_s < 1$ where the undoped state is a AF state. We obtain the following doping dependence of the SC order parameter:

$$\langle n_1 \rangle = \begin{cases} \sqrt{\rho(1-\rho_c)} & \text{for } \rho < \rho_c \\ \sqrt{\rho(1-\rho)} & \text{for } \rho > \rho_c \end{cases} \quad (5.7)$$

and the doping dependence of the of the AF order parameter:

$$\langle n_2 \rangle = \begin{cases} \sqrt{2(1-\rho_c)(\rho_c-\rho)} & \text{for } \rho < \rho_c \\ 0 & \text{for } \rho > \rho_c \end{cases} \quad (5.8)$$

These behaviors are depicted in Fig. (4).

FIG. 4. AF ($\langle n_2 \rangle$) and SC ($\langle n_1 \rangle$) order parameters versus density in the projected $SO(5)$ model.

We note several interesting features of the phase diagram. First of all, we can use the energy functional (4.7) as a starting point for a finite temperature classical fluctuation analysis, and estimate the transition temperature due to the classical fluctuations. Within such a framework, the 3D AF (T_N) and SC (T_c) transition temperatures are proportional to the stiffness of the spin and the phase fluctuations, which are in turn proportional to $\langle n_2 \rangle^2$ and $\langle n_1 \rangle^2$ respectively. Therefore, Fig. (4) gives an approximate estimate of the transition temperatures. For small ρ_c , we see that there is a sharp drop of T_N and a maximum of T_c at $\rho = 1/2$. The system is a AF insulator at doping $\rho = 0$ and a pure SC state for $\rho > \rho_c$. The reason for a maximum of T_c at $\rho = 1/2$ is due to the strong correlation of the charged bosons. The charge bosons have a hard-core interaction, therefore, they are insulating at both $\rho = 0$ and $\rho = 1$ and have maximal charge stiffness at $\rho = 1/2$. We can perform a rough translation of this optimal doping value in our effective model to the microscopic model. Since our effective model is defined on a unit cell with twice the lattice spacing of the microscopic model, $\rho = 1/2$ therefore describes one hole pair per four sites in the microscopic model, or a doping of $x = 1/4 = 25\%$ in the conventional language. This crude argument tends to overestimate the value for

optimal doping, since it neglects the effects of unpaired electrons. However, considering the crudeness of the estimate, it is still reasonably close to the optimal doping $x = 15\%$ observed in the LSCO family of high T_c superconductors.

In the regime of $0 < \rho < \rho_c$, the system is a coherent mixture of AF and SC order. For this entire range of densities, the system has a projected $SO(5)$ symmetry within the variational approximation discussed above. The projected $SO(5)$ symmetry manifests itself in terms of a infinite compressibility in the region $0 < \rho < \rho_c$ and, as we shall see in next section, a charge mode with a dispersion relation $\omega \sim k^2$. Since such a state is rather unusual, and maybe highly susceptible to density fluctuations, we would like to discuss more detailed physical properties in this region.

First let us comment on the fact that there are familiar physical systems whose uniform ground states are infinitely compressible. The free boson model is certainly such an example, and the density mode also has a $\omega \sim k^2$ dispersion relation. But the infinite compressibility is due to the absence of the interaction, which is not characteristic of the strongly interaction system considered here. A less trivial example is the spin 1/2 XXZ ferromagnetic Heisenberg model, given by the Hamiltonian,

$$\mathcal{H} = J \sum_{i,j} (S_i^x S_j^x + S_i^y S_j^y + \Delta S_i^z S_j^z) \quad (5.9)$$

where $J < 0$ and the sum extends over nearest neighbor sites of a square lattice. This model can be interpreted as quantum hard-core boson model, where the fully polarized spin down state could be identified with the vacuum of the bosons, the XY part of the Hamiltonian describes the hopping of the bosons and the last term describes the nearest neighbor attraction between the bosons if $\Delta > 0$. When $\Delta > 1$, the system is in the Ising limit, and the spontaneous breaking of the Z_2 symmetry implies phase separation of the bosons. On the other hand, when $0 < \Delta < 1$, the system is in the XY limit, and the ground state is a superfluid. Therefore, the anisotropy parameter describe the competition between superfluidity and phase separation. At $\Delta = 1$, the system has a $SU(2)$ symmetry and the dispersion relation becomes quadratic. Different directions of the ferromagnetic polarizations are degenerate and can be changed without any energy cost. Since the z component of the ferromagnetic polarization is identified with the total density of the hard-core bosons, the $SU(2)$ vacuum degeneracy implies infinite compressibility of the corresponding boson system for the entire range of boson densities $0 < \rho < 1$.

These two examples illustrates that there is nothing intrinsically pathological about having a system with infinite compressibility. The second example is more generic, and shows that uniform states with infinite compressibility can be obtained in systems on the verge of phase separation, and the infinite compressibility can be ensured by symmetry. Both of these properties are also shared by the projected $SO(5)$ model. These models are on the verge of phase separation into AF and SC phases, and the infinite compressibility is a result of the projected $SO(5)$ symmetry. It indicates that small perturbations, such as next nearest neighbor interactions, quantum fluctuations, and quenched disorder will be very important to determine the true ground state. With such perturbations, the ground state is expected to be unstable toward the experimentally reported textures such as the spin glass, stripes and incommensurate spin density waves.

Next let us investigate the phenomenological consequence of this remarkable property. One of the most puzzling properties of the high T_c superconductors is the constant chemical potential in the underdoped samples. For LSCO systems, where the doping level can be varied continuously by the Sr concentration, this effect has been dramatically observed in the ARPES experiments and the constant chemical potential persists from the weakly doped insulator to optimally doped superconductor [26]. In fact numerical calculations on the Hubbard model also reveal similar divergent behavior of the compressibility as the metal-insulator transition is approached from the metallic side [27].

The simplest explanation of the small chemical potential shift is a two phase mixture with different densities at a first order phase transition. If the system globally phase separates into two different spatial regions with different charge densities but the same free energy densities, the added charges only change the proportion of mixture of the two phases and do not change the energy, therefore, $\partial\mu/\partial\rho = 0$. However, this situation of global phase separation can certainly not occur in a system with long ranged Coulomb interaction and is ruled out in the real high T_c system.

A phenomenon possibly related to the tendency of phase separation is the formation of stripes [28–30]. A stripe state can be viewed as microscopic phase separation of AF and SC into alternating regions, where each region has different charge density and the same free energy density. However, a crucial difference between the global phase separation and this picture of microscopic phase separation is that the stripe state has infinitely many surfaces between AF and SC, and the surface energy makes a finite contribution to the total energy in the thermodynamic limit. In this picture, doping can be accomplished by converting AF stripes into SC stripes, thereby creating more surfaces separating AF and SC regions. Finite doping density therefore leads to a finite density of surfaces and the accumulated surface energy would in general lead to a shift of the chemical potential *under a generic situation*. Additional physical conditions are needed to ensure the constant chemical potential in the stripe phase.

Therefore, the absence of the chemical potential shift places a very strong constraint on possible theoretical explanations. The projected $SO(5)$ model proposed in this work offers a possible explanation for the absence of chemical potential shift. At a critical value of the chemical potential where the AF and SC states have degenerate energy density, we can have three situations, where the intermediate mixed states have higher, lower or degenerate energy compared to the AF and SC states. When the intermediate states have higher energy, the system will go through a first order phase transition at $\mu = \mu_c$ and this will lead to global phase separation into AF and SC regions. On the other hand, if the intermediate states have lower energy, there exists a range of chemical potential $\mu_{c1} < \mu < \mu_{c2}$ where the mixed phase has a uniform and continuously varying density. In this case, $\partial\mu/\partial\rho \neq 0$ is obtained. When the region $\mu_{c1} < \mu < \mu_{c2}$ shrinks to zero, we obtain the limiting $SO(5)$ symmetric case where the system is on the boundary between a first order transition and two second order phase transitions. In this case, $\partial\mu/\partial\rho = 0$ for a range of densities $0 < \rho < \rho_c$. Therefore, if we restrict to ground states where the density is not globally inhomogeneous, the absence of the chemical shift directly implies $SO(5)$ symmetry.

Within this model, we can therefore define a experimental procedure to measure one of the most crucial parameter of the theory, namely ρ_c . Using the experimental ARPES data for LSCO system we would identify ρ_c to be approximately the same as the optimal doping density. We recall that ρ_c is also a measure of the degree of the quantum spin fluctuation in the system. For the bi-layer materials such as YBCO and BISCO superconductors, the quantum spin fluctuation are stronger due to the inter-layer spin exchange, and we would predict that ρ_c should be less than the optimal doping value.

VI. COLLECTIVE MODES

Having discussed the ground state properties and the phase diagram of the model, we are now in a position to study the collective excitations of the model. We have argued that the ground state energy can remain $SO(5)$ symmetric despite the projection. However, the projection does affect the collective excitation spectrum near half-filling. Nonetheless, as we shall see, there remains a unique signature of the projected $SO(5)$ symmetry in the collective excitation spectra.

In principle, the collective excitation spectra can be obtained straightforwardly by studying the quadratic fluctuations around the mean field minima. The resulting quadratic boson Hamiltonian can be simply diagonalized. The main complication in the procedure is the hard-core boson constraint, which requires

$$t_\alpha^\dagger t_\alpha(x) + t_h^\dagger t_h(x) \leq 1 \quad (6.1)$$

for every site. There are several ways to implement this constraint rigorously. One is to follow the mapping from the one-component hard-core boson model to the XY model and generalize it to a multi-component hard-core boson model. One could also convert the above inequality constraint to an equality constraint by introducing a boson creation and annihilation operator for the singlet state. This approach will be implemented in the Appendix. For simplicity of presentation, here we shall adopt a less rigorous approach and introduce a on-site boson repulsion term

$$W \sum_x (t_\alpha^\dagger t_\alpha + t_h^\dagger t_h)^2 \quad (6.2)$$

to our Hamiltonian (2.11) and convert the hard-core constraint to a soft-core constraint. We shall show later that all results can be expressed in terms of the order parameter, which is implicitly dependent on W , but there is no explicit dependence on W . We have verified that all three methods give the same long wave length spectra for the collective modes in the limit of low boson density. In the next section, we shall present another calculation based on the continuum effective Lagrangian method, which also reproduces the same spectra.

To simplify presentation, we shall concentrate on the case where the ground state energy functional (4.7) is $SO(5)$ symmetric, *i.e.* for coupling constants $J_c = 2J_s \equiv 2J$ and $\tilde{\Delta}_c = \Delta_s \equiv \Delta$. We choose the direction of spontaneously broken symmetry to be $\langle t_x \rangle = \langle t_x^\dagger \rangle = x$ and $\langle t_h \rangle = \langle t_h^\dagger \rangle = y$. The extremal condition can be easily determined to be

$$x^2 + y^2 \equiv r^2 = \frac{4J - \Delta}{2W} \quad (6.3)$$

The combination $x^2 + y^2$ expresses the fact that the classical minimum is $SO(5)$ symmetric. We can therefore write $x = r \cos \alpha$ and $y = r \sin \alpha$. Expanding the boson operators as:

$$t_x = x + a_x, \quad t_y = a_y, \quad t_z = a_z, \quad t_h = y + a_h \quad (6.4)$$

we obtain the following quadratic Hamiltonian

$$\begin{aligned}
H = & (\Delta + 2Wr^2) \sum_x (a_x^\dagger a_x + a_h^\dagger a_h) + Wx^2 \sum_x (a_x^\dagger + a_x)^2 + Wy^2 \sum_x (a_h^\dagger + a_h)^2 \\
& - \frac{J}{2} \sum_{\langle x, x' \rangle} (a_x^\dagger(x) + a_x(x))(a_x^\dagger(x') + a_x(x')) - J \sum_{\langle x, x' \rangle} (a_h^\dagger(x) a_h(x') + h.c.) \\
& + 2Wxy \sum_x (a_h^\dagger(x) + a_h(x))(a_x^\dagger(x) + a_x(x)) \\
& - \frac{J}{2} \sum_{\langle x, x' \rangle} (a_y^\dagger(x) + a_y(x))(a_y^\dagger(x') + a_y(x')) - \frac{J}{2} \sum_{\langle x, x' \rangle} (a_z^\dagger(x) + a_z(x))(a_z^\dagger(x') + a_z(x')) \\
& + (\Delta + 2Wr^2) \sum_x (a_y^\dagger a_y + a_z^\dagger a_z)
\end{aligned} \tag{6.5}$$

We are in particular interested in the collective mode spectra for the AF insulating state with $\alpha = 0$, the mixed states with $0 < \alpha < \pi/2$ and the SC state with $\alpha = \pi/2$ and how they connect to each other.

From this quadratic Hamiltonian we can learn a number of important features. First we notice that the a_y and a_z modes are decoupled for all ranges of $0 \leq \alpha \leq \pi/2$, but most importantly, their dispersion relations are independent of α and given by

$$\omega(k) = v_s k \quad , \quad v_s = 2J \tag{6.6}$$

where $k \equiv a|\vec{k}|$ and a is the lattice constant. This is indeed a very remarkable property. At $\alpha = 0$, a_y and a_z modes are nothing but the transverse AF spin wave modes. AF spin waves are usually viewed as Goldstone modes and their existence is due to the AF long range order. However, as α changes continuously from 0 to $\pi/2$, the AF long range order continuously diminishes until it vanishes at $\alpha = \pi/2$. The reason that the properties of the a_y and a_z modes do not change at all is due to the $SO(5)$ symmetry of this model, since the diminishing AF order is compensated by the increasing SC order as the superspin angle α is varied. As we shall see, the a_x mode is the AF spin amplitude mode at $\alpha = 0$, but it becomes massless and degenerate with the a_y and a_z modes at $\alpha = \pi/2$. These three modes form a massless π triplet mode whose existence is purely a consequence of the SC order. Therefore, as α is continuously varied from 0 to $\pi/2$, the transverse AF spin wave modes gradually change their character to become the π triplet resonance of the SC state. As we shall see, for $\mu > \mu_c$, the π triplet mode becomes massive.

At the AF point $\alpha = 0$, the spin amplitude mode a_x is decoupled from the SC mode a_h and can be diagonalized separately. The dispersion for the spin amplitude mode has the conventional massive relativistic form for small k

$$\omega^2(k) = 16J^2(k^2/4 + m_x^2) \quad , \quad m_x^2 = \frac{Wx^2}{J} = \frac{4J - \Delta}{2J} \tag{6.7}$$

On the other hand, we have a massless SC Goldstone mode a_h with the following dispersion,

$$\omega(k) = Jk^2 \tag{6.8}$$

This mode is an important new prediction of the $SO(5)$ theory. It is the counterpart of the π resonance in the AF state. In the unprojected $SO(5)$ model, there are two such modes, with charge ± 2 , and they represent gapless fluctuations from AF to SC at half-filling. In the projected $SO(5)$ model, the charge +2 mode is projected out of the spectrum, however, the charge -2 mode remain massless at $\mu = \mu_c$. It is also a manifestation of the gapless fluctuation from AF to SC at half-filling, but the SC fluctuation is hole-like, rather than both hole and particle-like as in the unprojected case. We see again that a large Mott-Hubbard gap is fully compatible with gapless SC fluctuation at half-filling. Experimental detection of this mode could provide a important test of the projected $SO(5)$ symmetry.

The a_x and the a_h modes also decouple in the pure SC state with $\alpha = \pi/2$. However, their physical interpretation change. The a_x mode becomes gapless at this point with the same dispersion as in (6.6). Therefore, the three modes a_x , a_y and a_z form a gapless π triplet mode of the pure SC state, and represent the gapless fluctuation from SC to AF at $\mu = \mu_c$, but with a finite hole density ρ_c given in (5.6). The dispersion for the a_h mode is given by

$$\omega(k) = 2Jm_h k \quad , \quad m_h^2 = \frac{Wy^2}{J} = \frac{4J - \Delta}{2J} \tag{6.9}$$

and has the natural interpretation of a linearly dispersing phase Goldstone mode of the SC state.

In the intermediate mixed state with $0 < \alpha < \pi/2$, the a_x and the a_h modes are coupled. Diagonalization of these modes gives:

$$\frac{\omega^2(k)}{(4J)^2} = \begin{cases} (1 + m_h^2)k^2/4 + m_x^2 \\ (1 + m_h^2/m_x^2)k^4/16 \end{cases} \quad \begin{cases} m_x^2 = \frac{4J-\Delta}{2J} \cos^2 \alpha \\ m_h^2 = \frac{4J-\Delta}{2J} \sin^2 \alpha \end{cases} \quad (6.10)$$

The upper massive mode has predominantly spin amplitude character, and we see that the gap diminishes continuously until it reaches zero at $\alpha = \pi/2$ to become the massless π triplet mode. The lower mode has predominantly SC fluctuation character, and has a gapless $\omega \propto k^2$ dispersion. In the mixed region where both the AF and the SC order parameters are non-zero, one would naturally expect a gapless phase mode corresponding to the SC order. However, in an interacting boson system, the phase mode is expected to have linear dispersion on general ground. Therefore, what is surpassing and new here is not the gapless nature of the SC mode, but its *quadratic dispersion*. In order to locate the origin of the quadratic dispersion, we have perturbed the model away from the projected $SO(5)$ symmetric point so that a uniform mixed state is stabilized as a classical minimum. SC fluctuation around such a non- $SO(5)$ symmetric point is gapless and has linear dispersion. A quadratic dispersion is only realized at the $SO(5)$ symmetric point. Therefore, the quadratic dispersion is a unique signature of the projected $SO(5)$ symmetry in the entire range of densities $0 < \rho < \rho_c$! To understand the physical origin of this remarkable phenomenon, we notice that a boson system with gapless quadratic dispersion generally has infinite compressibility. This can be directly seen from the compressibility sum rule

$$\kappa \equiv \frac{\partial \rho}{\partial \mu} = \frac{1}{2} \lim_{k \rightarrow 0} \lim_{\omega \rightarrow 0} \chi(k, \omega) \sim \lim_{k \rightarrow 0} \frac{k^2}{\omega^2(k)} \quad (6.11)$$

where $\chi(k, \omega)$ is the dynamical density correlation function. Because of the quadratic dispersion relation, we can see explicitly that $\chi(k) \propto 1/k^2$ for small k , therefore, a infinite compressibility is obtained. On the other hand, a infinite compressibility implies that $\frac{\partial \mu}{\partial \rho} = 0$, *i.e.* the chemical potential is independent of doping. But this is exactly the prediction of the projected $SO(5)$ model! For $0 < \rho < \rho_c$, the chemical potential is pinned at the $SO(5)$ symmetric point $\mu = \mu_c$, where the superspin vector can point in any direction. To accommodate a long wave length fluctuation of the hole density, the system rotates into another degenerate minimum with a different superspin angle α and a different hole density. For this reason, the chemical potential does not change and the system is infinitely compressible.

VII. QUANTUM CORRECTIONS TO THE MEAN-FIELD SOLUTION

At the mean-field level, the ground-state energy of the Hamiltonian (2.11) with (6.2) depends on the AF and SC order parameters x and y only via their combination $r^2 = x^2 + y^2$ reflecting the $SO(5)$ invariance of the mean-field result. However, the zero-point energy of the bosons in the quadratic Hamiltonian gives a correction to the ground-state energy due to quantum fluctuations. (Calculations of the quantum fluctuation effects at the $SO(3)$ spin-flop transition have been studied in ref. [31]. As we will show below, this correction turns out to depend on x^2 and y^2 separately.

For the soft-constraint case, E_1 can be expressed as

$$E_1 = \frac{1}{2} \sum_k \sum_i \omega_i(k) - 2(\Delta + 2Wr^2) \quad (7.1)$$

where $\omega_i(k)$ are the four collective modes described in Sec. VI (although extended to all values of k in the BZ). In a systematic $1/s$ expansion, this correction to the ground state energy scales like $1/s$, and is therefore small in the semi-classical limit. Alternatively, E_1 can be seen as a small correction to the mean-field energy E_0 for small values of the parameter $\epsilon \equiv \frac{r^2 W}{2J} = 1 - \frac{\Delta}{4J}$. However, contrary to E_0 , E_1 also depends on the superspin angle α and thus produces a small $SO(5)$ -symmetry breaking.

We now evaluate the α -dependent part of Eq. (7.1) in the small- ϵ limit. We thus parametrize $\chi = 1 - 2\sin^2 \alpha$ ($-1 \leq \chi \leq 1$), differentiate the expression (7.1) with respect to χ , and expand it up to second order in ϵ . By further transforming $(\cos k_x + \cos k_y)/2 = 1 - q$ with $0 \leq q \leq 2$, the derivative of E_1 can be expressed as the sum of two terms

$$\frac{d}{d\chi} E_1 = E'_{1A} + E'_{1B}, \quad (7.2)$$

where

$$\frac{E'_{1A}}{E'_{1B}} = 2J \int_0^2 dq \mathcal{D}(q) \frac{G_A}{G_B}, \quad (7.3)$$

with

$$G_A \equiv \frac{((1 - \sqrt{q}) \epsilon)}{2\sqrt{q}} + O(\epsilon^2), \quad (7.4)$$

$$G_B \equiv -\frac{(\sqrt{q} - 1) (\chi \sqrt{q} - 1 - \chi - \sqrt{q}) \epsilon^2}{4 (1 + \sqrt{q}) q^{\frac{3}{2}}} + O(\epsilon^3), \quad (7.5)$$

and the density of states $\mathcal{D}(q)$ is defined as

$$\mathcal{D}(q) = \frac{1}{4\pi^2} \int dk_x dk_y \delta[q - 1 + (\cos k_x + \cos k_y)/2]. \quad (7.6)$$

Unfortunately, the terms of the ϵ expansion in G_B diverge when integrated over q . It is thus convenient to carry out the transformation $q = \epsilon z$ in G_B and then expand in powers of ϵ . We obtain

$$G_B = \frac{\sqrt{\epsilon}}{2} \left(\frac{1}{\sqrt{z+1+\chi}} - \frac{1}{\sqrt{z}} \right) + O(\epsilon). \quad (7.7)$$

For small ϵ , the integral in z can be extended to ∞ and we obtain from Eq. (7.3)

$$E'_{1B} = 2J \epsilon \int_0^\infty dz \mathcal{D}(z\epsilon) G_B = \frac{-(\sqrt{1+\chi} \epsilon^{3/2})}{\pi} + O(\epsilon^2 \log \epsilon). \quad (7.8)$$

While in evaluating Eq. (7.8) we only need the density of states at $q = 0$, $\mathcal{D}(0) = \pi^{-1}$, for the first term E'_{1A} one needs $\mathcal{D}(q)$ in the whole domain $0 \leq q \leq 2$. However, E'_{1A} is independent of χ and thus it merely fixes the value of the critical chemical potential. A numerical integration yields

$$E'_{1A} = 0.28 J \epsilon. \quad (7.9)$$

By integrating over χ Eqs. (7.9) and (7.8), we finally obtain the total contribution to the ground-state energy correction.

$$\frac{E_1}{2J} = 0.14 \chi \epsilon - \frac{2}{3\pi} (\epsilon (1 + \chi))^{3/2} + O(\epsilon^2 \log \epsilon) + \text{const.} \quad (7.10)$$

E_1 thus lifts the degeneracy as a function of χ and initially favors the pure superconducting phase ($\chi = -1$). A small chemical potential term $-\mu' y^2 = -\mu' r^2 (1 - \chi)/2$ with $\frac{\mu' r^2}{2J} = \frac{\mu'_c r^2}{2J} = -0.28 \epsilon + \frac{2}{3\pi} (2\epsilon)^{3/2}$ restores the degeneracy between the pure superconducting ($\chi = -1$) and the pure antiferromagnetic ($\chi = +1$) phases. However, due to the convexity of E_1 as a function of χ there is always a barrier ($\propto J\epsilon^{3/2}$) between the two phases since the mixed phase always has a higher energy. This means that at $\mu' = \mu'_c$ and for intermediate densities the system prefers to phase separate between the two pure phases rather than choosing the mixed phase. However, the important point is that this barrier remains small in the limit $U \rightarrow \infty$.

In view of the symmetry breaking effects of the quantum fluctuations, it would be interesting to see whether there is a limit when the the wave function (4.1) and the projected $SO(5)$ symmetry becomes exact. Rokhsar and Kotliar [32] have shown that this type of wave functions are actually exact in the limit of infinite dimensions. Therefore, besides the $1/s$ expansion, we could also use a $1/d$ expansion (where d is the space dimension) to systematically control the $SO(5)$ symmetry breaking quantum effects. Besides quantum fluctuations, there are also other symmetry breaking terms. Nearest-neighbor and next-nearest-neighbor Coulomb interactions also break the $SO(5)$ symmetry, however, their corrections to the ground state is concave, *i.e.* the energy of the intermediate states are lowered. Therefore, they can also lead to uniform mixed states in some region of the phase diagram. The detailed study of all these competing effects will be carried out in subsequent works.

VIII. LOW ENERGY EFFECTIVE LAGRANGIAN

While the projected $SO(5)$ model defined on a lattice enables us to make some connection to the underlying microscopic physics, for most discussions concerning the long wave length and low energy degrees of freedom, it is desirable to have a effective continuum Lagrangian. Such a formulation can be directly obtained by taking the long wave length limit of the projected bosonic model discussed previously. However, in order to make the connection to the unprojected $SO(5)$ model clearer, we shall motivate our discussion from the original $SO(5)$ effective model.

The effective Lagrangian for a fully $SO(5)$ symmetric model takes the form of

$$\mathcal{L} = \frac{\chi}{2}(\partial_t n_a)^2 - \frac{\rho}{2}(\partial_k n_a)^2 - V(n) \quad (8.1)$$

where χ measures the superspin susceptibility, ρ measures the superspin stiffness, $k = x, y$ denotes the spatial directions and $V(n)$ is a scalar function of the superspin magnitude n_a^2 only. There are three important symmetry breaking effects connected with the presence of a large Mott-Hubbard gap. First is an asymmetry in the scalar potential, which can be described by a additional term

$$V_g(n) = +\frac{g}{2}(n_1^2 + n_5^2) \quad (8.2)$$

which for positive g favors AF at half-filling. Second is the asymmetry between the spin (χ_s) and the charge (χ_c) susceptibilities, which modifies the kinetic energy to

$$\frac{\chi_s}{2}(\partial_t n_\alpha)^2 + \frac{\chi_c}{2}(\partial_t n_i)^2 \quad (8.3)$$

The last symmetry breaking effect is due to the chemical potential μ , which enters the Lagrangian as a gauge coupling in the time direction, and modifies the charge part of the kinetic energy to

$$\frac{\chi_c}{2}((\partial_t n_1 + \mu n_5)^2 + (\partial_t n_5 - \mu n_1)^2) \quad (8.4)$$

Combining these three symmetry breaking terms, we obtain

$$\begin{aligned} \mathcal{L} &= \frac{\chi_s}{2}(\partial_t n_\alpha)^2 + \frac{\chi_c}{2}((\partial_t n_1 + \mu n_5)^2 + (\partial_t n_5 - \mu n_1)^2) - \frac{\rho}{2}(\partial_k n_a)^2 - V(n) - \frac{g}{2}n_i^2 \\ &= \frac{\chi_s}{2}(\partial_t n_\alpha)^2 + \frac{\chi_c}{2}(\partial_t n_i)^2 + \mu\chi_c(n_5\partial_t n_1 - n_1\partial_t n_5) + \frac{\mu^2\chi_c - g}{2}n_i^2 - \frac{\rho}{2}(\partial_k n_a)^2 - V(n) \end{aligned} \quad (8.5)$$

In the presence of a large Mott-Hubbard gap, all these three symmetry breaking terms are of the order of U , *i.e.* $\chi_c^{-1} \sim g \sim \mu_c \sim U$. Therefore, this Lagrangian contains high energy degrees of freedom of the order of U . However, as already observed in [1], at $\mu = \mu_c = \sqrt{g/\chi_c}$, their effects cancel completely in the time-independent part of the Lagrangian, and the static potential is $SO(5)$ symmetric just as in the original unprojected model. We also observe that near the AF/SC transition point where $\mu \sim \mu_c$, the first order time derivative term is of the order of one. Furthermore, in the spirit of the low frequency and wave vector expansion, we only need to retain the first order time derivative term in the charge sector and can drop the second term in the above Lagrangian. Combining all these considerations, we obtain the following low energy effective Lagrangian near the AF/SC transition region, which is free of any parameters of the order of U :

$$\mathcal{L} = \frac{\chi_s}{2}(\partial_t n_\alpha)^2 + (n_5\partial_t n_1 - n_1\partial_t n_5) - \frac{\rho}{2}(\partial_k n_a)^2 - V(n) \quad (8.6)$$

This is exactly the Lagrangian counterpart of the $SO(5)$ projection procedure discussed previously in the Hamiltonian language. Dropping the second order time derivative terms removes half of the (high energy) degrees of freedom, and redefines the canonical conjugacy of the dynamical variables. In particular, the conjugate variable of n_1 is nothing but n_5 itself, since $p_1 = \delta\mathcal{L}/\delta\partial_t n_1 = 2n_5$. Standard quantization procedure requires the canonical commutation relation $[n_1, p_1] = i$, which in this case just reproduces equation (1.4). This confirms the fact that the $SO(5)$ projection does not change the form of the interaction potential, only the commutation relation between n_1 and n_5 .

It is easy to see that the low energy effective Lagrangian (8.6) produces exactly the same long wave length collective mode spectrum as the projected $SO(5)$ Hamiltonian (2.11) defined on a lattice. To facilitate the comparison, we take the $SO(5)$ potential to be

$$V(n) = -\frac{\delta}{2} \sum_a n_a^2 + \frac{W}{4} n_a^4, \quad \delta > 0 \quad (8.7)$$

Assuming broken symmetry in the n_1 and n_2 directions, we find that the n_3 and n_4 modes always decouple, and they have a linear spin wave dispersion relation with $v_s = \sqrt{\rho/\chi_s}$. The Euler-Lagrangian equations of motion gives the following dispersion relation for the n_1 and n_2 modes:

$$\omega^2 = \begin{cases} \frac{1}{4}\rho^2 k^4 \\ \frac{\rho}{\chi_s} k^2 + \frac{2\delta}{\chi_s} \end{cases} \quad (8.8)$$

for the AF state with $\langle n_1 \rangle = 0, \langle n_2 \rangle \neq 0$,

$$\omega^2 = \begin{cases} \frac{1}{2}\rho\delta k^2 \\ \frac{\rho}{\chi_s} k^2 \end{cases} \quad (8.9)$$

for the SC state with $\langle n_1 \rangle \neq 0, \langle n_2 \rangle = 0$, and

$$\omega^2 = \begin{cases} \frac{1}{4}(1 + \sin^2 \alpha / \cos^2 \alpha) \rho^2 k^4 \\ \frac{2\delta \cos^2 \alpha}{\chi_s} + (\frac{1}{2}\delta \rho \sin^2 \alpha + \frac{\rho}{\chi_s}) k^2 \end{cases} \quad (8.10)$$

for the mixed state with $\langle n_1^2 \rangle = \frac{\delta}{W} \sin^2 \alpha$ and $\langle n_2^2 \rangle = \frac{\delta}{W} \cos^2 \alpha$. These dispersion relations agree exactly with the lattice model results at the projected $SO(5)$ symmetric point if we make the following identification

$$\rho = 2J, \quad \chi_s = \frac{1}{2J}, \quad \delta = 2(4J - \Delta) \quad (8.11)$$

The effective Lagrangian can be easily used to discuss effects of $SO(5)$ symmetry breaking. The simplest form of symmetry breaking is increasing the chemical potential beyond the critical value μ_c , so that a pure SC state is realized. The chemical potential enters the effective Lagrangian through the gauge coupling in the time direction via the following substitution

$$\partial_t n_1 \Rightarrow \partial_t n_1 + \delta \mu n_5, \quad \partial_t n_5 \Rightarrow \partial_t n_5 - \delta \mu n_5, \quad (8.12)$$

where $\delta \mu \equiv \mu - \mu_c$ is the deviation of the chemical potential away from the critical value. In this case, the spin triplet excitations acquire a finite mass gap, with the following dispersion relation:

$$\omega^2(k) = \frac{\rho k^2}{\chi_s} + \frac{4(\mu - \mu_c)}{\chi_s} \quad (8.13)$$

and the mass gap increases with increasing doping in the SC state.

We summarize the behavior of the collective modes obtained in the previous two sections in Fig. (5).

FIG. 5. Evolution of the collective mode spectra as a function of density in the projected $SO(5)$ model. Fig. 5a shows the gap towards spin excitations. Charge excitations are gapless for the entire region of density, however, the dispersion relation changes from $\omega \sim k^2$ to $\omega \sim k$ at ρ_c , as indicated in Fig. 5b.

We see that while there are significant modifications of the collective mode spectra in the density regime $0 < \rho < \rho_c$ from the unprojected $SO(5)$ symmetry, the spectra beyond ρ_c is essentially identical to the behavior expected from the unprojected $SO(5)$ symmetry. This should be expected from our general considerations about the Gutzwiller projection without much detailed calculations. We argued that the only effect of the Gutzwiller projection is to change the quantum commutation relation between the SC components of the superspin n_1 and n_5 . However, for $\rho > \rho_c$, the system is in a pure SC phase where these components acquire classical expectation values. In this case, the modification of the quantum commutation relation does not have any significant effect. This argument can also be illustrated by a simple picture of a *chiral* $SO(5)$ sphere, as depicted in Fig. (6).

FIG. 6. Pictorial representation of a chiral $SO(5)$ sphere.

In this picture, the north and south poles represent the three AF directions, and the equatorial plane represent the SC directions. The sphere is perfectly $SO(5)$ symmetric. However, the chemical potential along the pole direction acts like a fictitious magnetic field which restricts the sense of the rotation in the SC plane. Small oscillations of a vector pointing close to the north pole enclose the fictitious magnetic flux, and can only execute chiral rotations. This amounts to the projection of the particle-pair states at half-filling. On the other hand, small oscillations of a vector pointing anywhere along the equator does not enclose the fictitious magnetic flux, and their dynamics is therefore unaffected by the projection. Dynamics of a vector pointing anywhere between the north pole and the equator is also partially affected by the projection, but the symmetry of the static potential bears a unique signature.

IX. CONCLUSION

The main purpose of this paper is to introduce the concept of projected $SO(5)$ models and discuss the properties of this model in connection with high T_c superconductivity. The projected $SO(5)$ model describes the low energy and long distance bosonic degrees of the freedom near the AF/SC transition. We showed that the Gutzwiller projection can be implemented analytically on every site in the $SO(5)$ theory. In the presence of a infinite Mott-Hubbard gap, we show that static properties of the model can remain $SO(5)$ symmetric, while the modification of the dynamics can be completely cast into a non-trivial commutation relation between the two SC components of the $SO(5)$ superspin. Unlike the unprojected $SO(5)$ models which can only have the full dynamic $SO(5)$ symmetry at half-filling, the projected $SO(5)$ model can have static $SO(5)$ symmetry at a critical value of the chemical potential μ_c and for a finite range of doping $0 \leq \rho \leq \rho_c$. At $\rho = 0$, the system has a AF ground state and zero compressibility. In the intermediate regime $0 < \rho < \rho_c$, the system has mixed AF and SC order and infinite compressibility. For $\rho > \rho_c$, the system has a pure SC ground state, the SC order parameter rises to a maximal value before it decreases with doping. At the projected $SO(5)$ symmetric point, we can understand precisely the evolution of the collective modes. On the AF side, we have two gapless spin wave modes and a gapless charge mode describing the gapless fluctuation from AF

to SC. In the intermediate density regime $0 < \rho < \rho_c$, the physical properties of the spin waves remain unchanged, while the massive spin amplitude mode gradually decreases its energy and merges with the two spin wave modes at $\rho = \rho_c$. The charge mode in the intermediate density regime is gapless, but has quadratic dispersion relation, which is a unique signature of the projected $SO(5)$ symmetry. For $\rho > \rho_c$, the charge mode is gapless with linear dispersion relation, and the π triplet spin mode becomes massive, and gradually increases its energy with increasing doping. In this regime, the behavior of the collective modes are identical to the unprojected $SO(5)$ model.

This very simple model can form the basis to understand many novel and puzzling properties of the high T_c superconductors in a unified framework. It points out a route from AF to SC through a gradual rotation of the superspin angle. At the projected $SO(5)$ symmetry point the mean field energy is independent of the superspin angle, and therefore it offers an explanation of the absence of the chemical potential shift in the underdoped regime without global phase separation. It predicts a phase diagram which is qualitatively consistent with the observed phase diagram in the high T_c materials. In the underdoped regime of the phase diagram, the system have large AF and SC fluctuations, and these fluctuations can be responsible for the pseudogap physics observed in these materials.

There are many possible directions to carry out this line of research in the future. The most important issue is to understand the precise nature of the intermediate state in the regime $0 < \rho < \rho_c$. Since the system has infinite compressibility in this regime, different small perturbation may select different ground states. Such perturbing effects might include quantum fluctuations and longer ranged interactions. In particular, we would like to investigate the possibility that these perturbations might lead to the formation of incommensurate order or stripes.

In this work, we have discussed extensively the collective fluctuations in the long wave length limit. Due to the definitions of our effective lattice model, the $k \rightarrow 0$ limit corresponds to the $k \rightarrow 0$ limit in the SC correlation functions and the $k \rightarrow (\pi, \pi)$ limit of the AF spin correlation functions. Within the $SO(5)$ theory, the π resonance in the SC state is viewed as the $SO(5)$ symmetry partner of the $k \rightarrow 0$ Goldstone mode of the SC phase fluctuation. While the commensurate neutron resonance mode is observed in both YBCO and BISCO superconductors, all high T_c systems also have incommensurate spin fluctuations. How can these features be explained within the current theoretical model?

The fact that LSCO and YBCO have very different Fermi surface shapes and yet have similar incommensurate magnetic peaks strongly suggests that the incommensurate peaks are not sensitive to Fermi surface effects and should be explainable within an effective bosonic model. Let us recall that the collective mode of a superfluid boson system consists of linearly dispersing phonon branch and another roton branch with a minimum located at the inverse inter-particle spacing. So far, we have only studied the phonon branch of the charged bosons. By analogy, the roton branch should also exist, with a wave vector determined by the density of the charged bosons or doping. Within the $SO(5)$ theory, while the commensurate neutron resonance can be viewed as the $SO(5)$ partner of the SC phase mode, the incommensurate magnetic peaks can be viewed as the $SO(5)$ partner of the roton minimum of the charged bosons. A detailed quantitative analysis of this picture will be carried out in the future.

However, while the ground state in the doping range $0 < \rho < \rho_c$ may depend sensitively on small perturbation effects, at finite temperature, these perturbation effects should be small and the system should display more universal properties. We have shown that the projected $SO(5)$ symmetry should be valid for the entire doping range $0 < \rho < \rho_c$, and we shall quantitatively study the manifestation of this symmetry at finite temperature, and see if the projected $SO(5)$ symmetry can give a universal explanation of the pseudogap physics.

Note Added: After completing this work, we received a very interesting paper by Coen van Duin [35], in which he also observed the “remnant $SO(5)$ behavior in the large U limit”.

APPENDIX A: SLAVE BOSON RESULTS

Alternatively, one can enforce the hard-core constraint (6.1) by introducing an additional “slave” boson for each lattice site. The presence of this boson ($e(x)$) indicates that the lattice site x is in the singlet state. The “less or equal” hard-core condition (6.1) is replaced with the equality constraint

$$Q(x) = \sum_{\alpha} t_{\alpha}^{\dagger}(x) t_{\alpha}(x) + t_h^{\dagger}(x) t_h(x) + e^{\dagger}(x) e(x) - q = 0, \quad (\text{A1})$$

with $q = 1$. Since in physical states one always has one and only one boson per lattice sites, destruction (creation) of a boson t_a ($t_a^{\dagger}$) must always be accompanied by creation (destruction) of the empty boson $e^{\dagger}$ (e). In this way, the *physical* operators for creating (destroying) a triplet ($a = x, y, z$) or a hole pair ($a = h$) acquire the form $t_a^{\dagger} e$ ($t_a e^{\dagger}$). The advantage of this method is that the constraint can be enforced exactly (at least in principle) by introducing an additional time-independent field $\lambda(x)$ at each lattice site, by adding to the Hamiltonian a term $-\lambda(x)Q(x)$ and by integrating over the $\lambda(x)$ on the imaginary axis. The whole Hamiltonian (2.11) thus takes the form (apart for a constant)

$$\begin{aligned} H_{sb} = & - \sum_x \lambda(x) Q(x) + \Delta_s \sum_{x,\alpha} t_{\alpha}^{\dagger}(x) t_{\alpha}(x) + \tilde{\Delta}_c \sum_x t_h^{\dagger}(x) t_h(x) \\ & - J_s/2 \sum_{\langle x,x' \rangle, \alpha} (t_{\alpha}^{\dagger}(x) e(x) + h.c.) (t_{\alpha}^{\dagger}(x') e(x') + h.c.) \\ & - J_c/2 \sum_{\langle x,x' \rangle} \left(t_h^{\dagger}(x) e(x) e^{\dagger}(x') t_{\alpha}(x') e(x') + h.c. \right). \end{aligned} \quad (\text{A2})$$

In practice, one starts with a mean-field approximation and expands the boson operators around their mean-field values as in Sec. VI. This expansion can be rigorously controlled by generalizing the constraint (A1) to large values of q , whereby one scales $J_{c/s} \rightarrow J_{c/s}/s$ (cf. Refs. [33,34]). Physically, this corresponds to allow for a large number of bosons to be present at each site and thus to have a large value for the total spin, or more precisely for the SO(5) quantum number s , at each site. The mean-field result thus corresponds to the $q \rightarrow \infty$ limit, while the quadratic expansion corresponds to the first $1/q$ correction.

At the mean-field level, the constraint is fulfilled exactly and indeed one obtains the same result and the same phase diagram as the variational ansatz (4.1) discussed in Sec. V. By expanding the bosons quadratically around the mean-field one obtains the same modes as for the soft-core Hamiltonian with a similar dispersion. (Here, we restrict again to the SO(5)-symmetric case). Specifically, in the mixed phase one obtains two spin-wave modes with dispersion

$$\omega(k) = \frac{4J + \Delta}{4} k, \quad (\text{A3})$$

one massive spin-amplitude mode

$$\omega(k)^2 = (16J^2 - \Delta^2) \cos^2 \alpha + O(k^2), \quad (\text{A4})$$

and a quadratic mode

$$\omega(k) = \frac{4J + \Delta}{8 \cos \alpha} k^4. \quad (\text{A5})$$

In the pure superconducting phase, one has a π -triplet with dispersion

$$\omega(k) = \frac{4J + \Delta}{4} k \quad (\text{A6})$$

and the SC Goldstone mode with dispersion

$$\omega(k)^2 = \frac{16J^2 - \Delta^2}{4} k^2 \quad (\text{A7})$$

These results coincide with the ones of the soft-constraint approximation Eqs. (6.6) to (6.10) in the limit of small $4J - \Delta$, i. e. , for low boson density.
